Review

Intrauterine contraceptive device-associated actinomycotic abscess and *Actinomyces* detection on cervical smear

PhD Anthony S. Fiorino

Objective

To summarize clinical features and treatments in reported cases of actinomycotic pelvic abscess occurring in women using intrauterine contraceptive devices (IUD), and to review detection of *Actinomyces* by cervical smear.

Data Sources

The English-language medical literature accessed through MEDLINE.

Methods of Study Selection

We identified 92 cases of actinomycotic abscesses associated with IUD use in 63 case reports. In addition, 31 studies of *Actinomyces* detection were found, 16 of which were studies of Papanicolaou smear-based detection.
Data Abstraction and Synthesis
Data regarding clinical presentation and treatment were culled from case reports, whereas detection rates of Papanicolaou smear and other methods were obtained from studies of *Actinomyces* detection. The average patient was 37 years old, had been using an IUD for 8 years, and presented with abdominal pain, weight loss, vaginal discharge, and fever. Laboratory studies commonly revealed anemia, leukocytosis, and an elevated erythrocyte sedimentation rate. Most of these patients underwent operative procedures, usually hysterectomy and salpingo-oophorectomy. High-dose penicillin was found to be an effective antibiotic. Detection rates of organisms on Papanicolaou smear were somewhat variable; use of other detection methods, including endometrial biopsy, culture, and immunofluorescence, did not improve this variability.

Conclusions
Pelvic actinomycosis associated with the use of IUDs can mimic pelvic malignancy; for that reason, it is often treated surgically. However, if the diagnosis of actinomycosis can be obtained preoperatively, antibiotic treatment may lead to complete resolution. The Papanicolaou smear may be useful in evaluating such patients.
